

Nonlinear Intergenerational Mobility: Returns to Human Capital

December 26, 2025

Abstract

We study how non-linear returns to human capital shape intergenerational mobility. We develop an intergenerational model of parental investment in which the market return to human capital is increasing and features discrete thresholds. In this environment, the mapping from parental income into optimal investment becomes highly non-linear: small differences in parental income can induce large, discrete changes in investment choice. As a result, families sort endogenously into low- and high-investment regimes, generating persistent inequality and reduced intergenerational mobility, particularly at the top of the income distribution.

1 Introduction

A central empirical regularity in the intergenerational mobility literature is the non-uniform transmission of income between parents and children along the income distribution. This insight is emphasized by empirical work showing that the relationship between parental and child income is inherently non-linear, even under canonical log-log specifications (Chetty, Hendren, Kline, and Saez 2014). Consistent with this evidence, a growing body of research documents direct non-linearities in intergenerational income with substantially higher persistence in specific segments of the parental income distribution. For the Nordic economies, Bratsberg, Røed, Raaum, Naylor, Jäntti, Eriksson, and Österbacka (2007) find a concave intergenerational relationship at the bottom and a convex one at the top of the distribution. At the international level, Berrittella and Dardanoni (2016) document significant heterogeneity in intergenerational transmission, while for Latin America recent evidence shows that, although mobility is relatively high in the middle of the distribution, intergenerational persistence is considerably stronger at the top (Leites, Ramos, Rodríguez, and Vilá 2022; Cortés Orihuela, Díaz, Gutiérrez Cubillos, Troncoso, and Villarroel 2024; Britto, Fonseca, Pinotti, Sampaio, and Warwar 2022).

These empirical patterns pose a challenge to standard models of intergenerational mobility (Becker and Tomes 1979; Solon 1999; Solon 2004). In the canonical human capital investment framework, parental decisions respond smoothly and continuously to changes in income, generating linear relationships between parents' and children's incomes. As a result, these models have difficulty explaining why intergenerational persistence is particularly high at the upper tail of the income distribution. This paper starts from this puzzle and proposes a mechanism that endogenously generates non-linearities in intergenerational income transmission.

A plausible explanation for the presence of non-linearities in intergenerational mobility is that incentives to invest in human capital are not constant along the income distribution. In particular, if market returns to skills increase disproportionately beyond certain levels of human capital, there is a point where small differences in parental resources can translate into amplified differences in investment decisions and, consequently, into higher intergenerational income persistence in the upper part of the distribution of income. In this sense, the profound changes observed in wage structures since the 1980s provide a relevant empirical context for studying the origins of these non-linearities. Since the 1980s, wage inequality has increased substantially in both developed and developing economies, a phenomenon that a central explanation attributes to skill-biased technological change, which has increased the relative demand for more skilled workers (Lawrence F. Katz and Murphy 1992; Krusell, Ohanian, Ríos-Rull, and Violante 2000; Card and DiNardo 2002; Buera, Kaboski, Rogerson, and Vizcaino 2021), in this context, Juhn, Murphy, and Pierce (1993) argue that a substantial fraction of the increase in wage inequality can be attributed to higher returns to skill. Increasing returns to human capital can arise from several mechanisms: the emergence of superstar economies (Rosen 1983; Autor, Dorn, Lawrence F Katz, Patterson, and Van Reenen 2020), for instance, has increased demand for highly skilled workers in talent-intensive firms, disproportionately raising returns at the top of the human capital distribution, so that reaching sufficiently high levels of human capital allows access to occupations and firms where accumulated skills are especially valued and thus more highly rewarded.

On the other hand, accumulating human capital beyond certain thresholds facilitates access to elite schools and universities, as well as to employers at more productive firms that differentially value such credentials (Dale and Krueger 2002; Zimmerman 2019; Chetty, Deming, and Friedman 2025). Access to these environments not only directly increases the returns to invested human capital, but also enables the formation of valuable networks and connections (Bavaro and Patriarca 2022), which can amplify initial disparities and generate inefficiencies associated with talent misallocation (Bandyopadhyay, King, and Tang 2019). Consistent with these mechanisms, empirical evidence shows that incomes at the top of the distribution largely reflect high returns to human capital. Executive compensation has increased substantially over recent decades (Gabaix and Landier 2008), suggesting that the market rewards individuals with high

levels of skill and human capital in an increasingly convex manner. Complementarily, using U.S. administrative data, Smith, Yagan, Zidar, and Zwick (2019) document that a predominant share of income at the top percentile comes from pass-through business income associated with labor and entrepreneurial skills rather than from financial capital.

Changes in the structure of labor market returns not only reshape income distribution within a generation but also influence intergenerational mobility by affecting how economic advantages are transmitted from parents to children. Empirically, this is reflected in a well-documented pattern across modern economies: the positive association between income inequality and intergenerational persistence, commonly referred to as the *Great Gatsby Curve* (Krueger 2012; Corak 2013). This relationship raises concerns about equality of opportunity and the extent to which income differences reflect persistent advantages rather than individual merit. To understand the *Great Gatsby Curve*, it is necessary to move beyond aggregate correlations and examine the microeconomic channels through which inequality translates into persistent outcomes. A prominent explanation emphasizes the role of changes in the structure of returns to human capital in shaping parental investment decisions. From this perspective, the *Great Gatsby Curve* can be seen as the aggregate outcome of heterogeneous parental responses to non-linear returns to skill. This view connects with a broader literature that seeks to rationalize the inequality and mobility relationship from multiple angles (Becker, Kominers, Murphy, and Spenkuch 2018; Durlauf and Seshadri 2018; Bouchard St-Amant, Marceau, and Garon 2024), highlighting parental investment as a key transmission channel. In particular, when returns to skill investment are increasing and feature thresholds, rising wage inequality not only widens income dispersion within a generation but also amplifies differences in parental investment behavior. This mechanism strengthens intergenerational persistence, especially at the top of the income distribution, where access to high-return opportunities becomes feasible.

To formalize these ideas, we develop an intergenerational model of human capital investment, building on the classic framework of Becker and Tomes (1979) with simplifications following Solon (1999), and incorporating a structure of differentiated returns to human capital investment. This extension alters optimal parental investment decisions and, consequently, the properties of intergenerational income transmission. The model contributes to the literature on intergenerational mobility in three ways. First, it provides a simple intergenerational framework in which non-linear returns to human capital generate endogenous non-linearities in income transmission. Second, it shows how small differences in parental income can lead to discrete changes in investment behavior, generating higher persistence at the top of the income distribution. Third, it offers a mechanism consistent with the empirical patterns summarized by the *Great Gatsby Curve*. As a result, the parental investment problem features non-convexities associated with the existence of differentiated return regimes to human capital. In par-

ticular, parents face a low-return regime at low levels of investment and a high-return regime once a given threshold is surpassed. In this environment, there exists a level of parental income at which parents are indifferent between choosing an investment that keeps them in the low-return regime and an investment that allows access to the high-return regime. Given this point of indifference, intermediate levels of investment between the two regimes are strictly dominated and are not chosen in equilibrium. This structure introduces a bifurcation point at which small changes in parental income can induce large, discrete adjustments in children’s human capital investment.

This mechanism is conceptually analogous to that arising in classic models of non-linear taxation (Burtless and J. Hausman 1978; J. A. Hausman 1985), such as negative income tax (NIT) programs. In those models, the introduction of transfers with discontinuous marginal tax rates generates non-convex budget sets, implying that certain ranges of labor supply never constitute a global optimum under convex preferences. Similarly, in our framework, the presence of thresholds in human capital returns implies that certain intermediate levels of parental investment are strictly dominated, concentrating decisions in low- or high-investment regimes. This pattern contributes to the formation of economic dynasties and to lower intergenerational mobility, particularly at the top of the income distribution.

Within the intergenerational mobility literature, a growing set of studies moves beyond average measures of persistence to characterize non-linearities in income transmission across the parental income distribution and to shed light on the relationship between inequality and mobility summarized by the Great Gatsby Curve. A prominent contribution in this line is Bratsberg, Røed, Raaum, Naylor, Jäntti, Eriksson, and Österbacka (2007), who document non-linear intergenerational income transmission in Denmark, Finland, and Norway. At the bottom of the distribution, they find a concave relationship between parental and children’s incomes, consistent with models featuring credit constraints on human capital investment (Becker and Tomes 1986; L. J. Lochner and Monge-Naranjo 2011; Caucutt and L. Lochner 2020). At the top of the distribution, the authors point to the possibility of a convex relationship, motivated by increasing returns to skill investment at high levels of human capital. The interaction of these two mechanisms yields an S-shaped intergenerational relationship, characterized by lower mobility at both the bottom and the top of the parental income distribution. However, their analysis does not incorporate an explicit parental investment mechanism capable of explaining how increases in parental income translate into discrete changes in investment decisions and, consequently, into endogenous shifts in the slope of intergenerational transmission at the top of the distribution.

Our approach is also related to Becker, Kominers, Murphy, and Spenkuch (2018), who show that children’s income is convex in parental human capital and that economic dynasties may emerge. In their framework, convexity arises from complementarities in human capital production (Cunha and Heckman 2007), whereby parental human capital

increases productivity both in the labor market and in children’s skill formation. In contrast, in our model income convexity and intergenerational persistence emerge from differences in market returns to human capital beyond certain investment thresholds, even in the absence of technological complementarities in skill production. In this sense, our mechanism provides an alternative and complementary explanation for the emergence of economic dynasties and non-linearities in the intergenerational elasticity of income.

Finally, this paper relates to Solon (2004), who shows that global increases in returns to human capital, combined with higher levels of inequality, raise the intergenerational elasticity of income in a manner consistent with the Great Gatsby Curve. However, in that framework inequality is treated as exogenous, and the role of parental investment decisions or endogenous changes in the structure of returns to human capital is not examined. In this respect, our model complements this literature by endogenizing parental investment responses to changes in returns and by showing how these responses can generate persistent non-linearities in intergenerational mobility.

2 Threshold Returns and Discrete Parental Investment Choices

Consider a family with two generations. The parent lives in period $t - 1$ and decides how to allocate income between own consumption and investment in the human capital of the child, who lives in period t . Higher investment in human capital today translates into higher income for the child in the future.

In the simplest case, the child’s income increases proportionally with parental investment: each additional unit invested generates the same marginal return, regardless of the investment level. In such an environment, changes in the return to human capital investment affect all families in a similar way and do not qualitatively alter optimal decisions across agents. This paper instead explores a different mechanism. Suppose that returns to human capital investment are not constant but increase beyond a certain investment threshold. In particular, above a level $\bar{I}$, each additional unit invested yields a higher marginal return than the previous one.

This structure introduces a non-linearity in intergenerational income transmission. The parent maximizes a utility function that is a weighted sum of two concave components: utility from own consumption and utility derived from the child’s future income. Under these preferences, indifference curves are convex.

As illustrated in Figure 1, the presence of a *kink* in market returns to human capital can generate discontinuous behavior and discrete changes in optimal parental investment. For a given level of parental income, two global optima may coexist: one located in the low-return regime and another that exceeds the threshold $\bar{I}$ and benefits from

the discrete increase in marginal returns. A marginal increase in parental income shifts the global optimum to the high-return regime, while a marginal decrease leads the parent to choose the low-return regime. Importantly, under concave preferences over consumption and the child’s income, the parent never chooses to invest exactly $\bar{I}$, as such an investment does not allow the parent to exploit increasing marginal returns and is therefore strictly dominated.

This figure complements the conjecture proposed by Bratsberg, Røed, Raaum, Naylor, Jäntti, Eriksson, and Österbacka (2007) regarding convex non-linearities in intergenerational income relationships, which we endogenize through discrete changes in human capital returns beyond a certain level of parental investment.

This mechanism is conceptually analogous to that arising in classic models of non-linear taxation with transfers, such as negative income tax (NIT) programs (Burtless and J. Hausman 1978; J. A. Hausman 1985). In those models, the presence of segments with discontinuous marginal tax rates generates non-convex budget sets. As a consequence, under convex indifference curves, certain ranges of labor supply never constitute an optimal solution: individuals choose corner solutions associated with different tax regimes, and small changes in non-labor income or policy parameters can induce discrete adjustments in labor supply decisions.

Similarly, in our framework, thresholds in human capital returns induce non-convexities in the parental investment problem. The existence of a discrete change in marginal returns implies that certain intermediate levels of investment are strictly dominated and therefore never chosen in equilibrium. As a result, parental decisions concentrate in two well-defined regimes: a low-investment regime associated with low marginal returns, and a high-investment regime that allows access to increasing returns to human capital. As in non-linear tax models, small variations in parental income can generate discrete changes in the optimal decision, shifting the family from one regime to the other.

It is important to note that this mechanism differs from models of *bunching* under progressive taxation (Saez 2010). In that context, budget sets remain convex, there is always a unique global optimum, and the *kink* itself may constitute an optimal choice under certain preference configurations. In contrast, in our environment—much like in models with non-convex budget sets—the threshold $\bar{I}$ is never chosen in equilibrium under concave preferences, as it does not allow agents to fully exploit increasing marginal returns. This structure generates persistent polarization in parental investment and contributes to the formation of economic dynasties, reducing intergenerational mobility, particularly at the upper end of the income distribution.

Figure 1: Optimal parental investment decisions under non-linear returns to human capital. The figure illustrates the coexistence of two global optima, one in the low-return regime and another exceeding the threshold $\bar{I}$ under convex indifference curves. This result complements Figure 1(b) in Bratsberg, Røed, Raaum, Naylor, Jäntti, Eriksson, and Österbacka (2007) by endogenizing the conjecture of a convex relationship in intergenerational income transmission through discrete changes in returns to human capital investment.

3 Modelo

Consider a family with two generations. The parent lives in period $t - 1$ and decides how to allocate income y_{t-1} between own consumption c_{t-1} and investment in the child's human capital, I_{t-1} , who lives in period t . Higher investment in human capital translates into higher income for the child in the future.

We assume that the child's income features a discrete change in returns to human capital investment. In particular, the marginal return to human capital equals r for investment levels below a threshold $\bar{I}$, and increases to $r' > r$ once investment exceeds this threshold. The term e_t captures components of the child's human capital that are inherited and exogenous to parental investment decisions.

Under this structure, the child's income is given by

$$y_t = (1 + r)I_{t-1} + e_t + (r' - r) \max\{0, I_{t-1} - \bar{I}\}.$$

Following the simplified framework of Solon (1999), the parent maximizes a utility function that depends on own consumption and the child's future income, weighted by an altruism parameter $\alpha \in (0, 1)$,

$$\alpha \log(c_{t-1}) + (1 - \alpha) \log y_t.$$

As illustrated in Figure 1, the presence of discrete changes in human capital returns, combined with concave preferences over consumption and the child's income, implies convex indifference curves. This structure generates a situation in which it is not optimal for the parent to invest exactly at the point where the regime change in returns occurs, nor in its neighborhood. As a result, the intergenerational income transmission technology exhibits an inherent non-linearity.

Local solutions to the parent's problem are obtained by solving the maximization problem separately within each segment of the linear relationship between the child's income and human capital investment, under the assumption that each segment extends over the entire investment domain—that is, using the virtual relationships associated with each regime. For any of these solutions to constitute a global optimum, the resulting investment level must lie within the domain of the corresponding segment. Once the candidate global optima are identified, the associated indirect utilities are compared.

It is more informative, however, to directly characterize the level of parental income at which the parent is indifferent between investing under the low-return regime and under the high-return regime. This indifference point determines a threshold beyond which small changes in parental income can induce discrete changes in optimal investment in the child's human capital.

Given a technological regime with constant return $\rho \in \{r, r'\}$, the parent solves the following local problem:

$$\max_{I \in [0, y_{t-1}]} \alpha \log(y_{t-1} - I) + (1 - \alpha) \log((1 + \rho)I + e_t).$$

The first-order condition is

$$\frac{\alpha}{y_{t-1} - I} = \frac{(1 - \alpha)(1 + \rho)}{(1 + \rho)I + e_t},$$

which yields the locally optimal investment

$$I^*(\rho) = (1 - \alpha)y_{t-1} - \frac{\alpha}{1 + \rho}e_t.$$

Evaluating the objective function at $I^*(\rho)$ and using the first-order condition, the indirect utility associated with regime ρ can be written as

$$V(\rho) = \log((1 + \rho)y_{t-1} + e_t) - \alpha \log(1 + \rho) + \alpha \log \alpha + (1 - \alpha) \log(1 - \alpha).$$

The last term is constant in ρ and therefore irrelevant for regime comparison.

The parent is indifferent between investing under the low-return regime r and the high-return regime $r' > r$ when

$$V(r) = V(r').$$

Using the closed-form expression for indirect utility, this condition can be written as

$$\log \frac{(1+r')y_{t-1} + e_t}{(1+r)y_{t-1} + e_t} = \alpha \log \frac{1+r'}{1+r}. \quad (\text{IC})$$

Exponentiating both sides yields

$$\frac{(1+r')y_{t-1} + e_t}{(1+r)y_{t-1} + e_t} = \left(\frac{1+r'}{1+r} \right)^\alpha.$$

Multiplying and rearranging terms gives

$$(1+r')y_{t-1} + e_t = \left(\frac{1+r'}{1+r} \right)^\alpha [(1+r)y_{t-1} + e_t].$$

Collecting terms in y_{t-1} ,

$$\left[(1+r') - (1+r) \left(\frac{1+r'}{1+r} \right)^\alpha \right] y_{t-1} = e_t \left[\left(\frac{1+r'}{1+r} \right)^\alpha - 1 \right].$$

Therefore, the level of parental income that leaves the parent indifferent between the two regimes is given by

$$y_{t-1}^{\text{ind}}(e_t) = \frac{e_t \left[\left(\frac{1+r'}{1+r} \right)^\alpha - 1 \right]}{(1+r') - (1+r) \left(\frac{1+r'}{1+r} \right)^\alpha}$$

Since $r' > r$ and $\alpha \in (0, 1)$, both the numerator and the denominator are strictly positive, ensuring that $y_{t-1}^{\text{ind}}(e_t) > 0$. Consequently, for $y_{t-1} < y_{t-1}^{\text{ind}}(e_t)$ the parent prefers to invest under the low-return regime, while for $y_{t-1} > y_{t-1}^{\text{ind}}(e_t)$ it is optimal to jump discretely to the high-return regime. This mechanism introduces a discontinuity in optimal investment and generates a non-linearity in the intergenerational income transmission technology.

For this income level to act as an effective (*binding*) regime-switching threshold, it must be the case that, when evaluated under the low-return regime, the optimal investment choice reaches the kink in the technology. In particular, parental income $y_{t-1}^{\text{ind}}(e_t)$ must be sufficiently low such that optimal investment in the first segment equals $\bar{I}$.

Recalling that under the low-return regime optimal investment is given by

$$I^*(y_{t-1}, e_t) = (1-\alpha)y_{t-1} - \frac{\alpha}{1+r}e_t,$$

the condition for the threshold $y_{t-1}^{\text{ind}}(e_t)$ to be economically relevant is

$$I^*(y_{t-1}^{\text{ind}}(e_t), e_t) \leq \bar{I}.$$

When this condition holds, the parent is exactly at the boundary of the first segment of the technology, and the preference crossing between regimes translates into an effective switch in the investment regime. Otherwise, if for $y_{t-1}^{\text{ind}}(e_t)$ optimal investment under the low-return regime exceeds $\bar{I}$, the indifference point has no economic content, since the technological constraint is not binding and the parent would already be operating in the high-return segment.

With this structure, the intergenerational income transmission technology can be written in reduced form by substituting optimal investment choices into the child's income equation. Since regime choice depends on parental income, two distinct intergenerational relationships emerge.

For parents with income below the indifference threshold, $y_{t-1} \leq y_{t-1}^{\text{ind}}(e_t)$, optimal investment occurs under the low-return regime r ,

$$I^*(r) = (1 - \alpha)y_{t-1} - \frac{\alpha}{1 + r}e_t.$$

Substituting into the child's income equation yields

$$\begin{aligned} y_t &= (1 + r)I^*(r) + e_t \\ &= (1 + r)(1 - \alpha)y_{t-1} + \alpha e_t. \end{aligned}$$

For parents with income above the threshold, $y_{t-1} > y_{t-1}^{\text{ind}}(e_t)$, the global optimum involves investing under the high-return regime r' ,

$$I^*(r') = (1 - \alpha)y_{t-1} - \frac{\alpha}{1 + r'}e_t.$$

In this case, the child's income is given by

$$\begin{aligned} y_t &= (1 + r')I^*(r') + e_t \\ &= (1 + r')(1 - \alpha)y_{t-1} + \alpha e_t. \end{aligned}$$

As a result, the intergenerational income relationship takes a non-linear, piecewise form, with different slopes depending on the level of parental income:

$$y_t = \begin{cases} (1 + r)(1 - \alpha)y_{t-1} + \alpha e_t, & \text{if } y_{t-1} \leq y_{t-1}^{\text{ind}}(e_t), \\ (1 + r')(1 - \alpha)y_{t-1} + \alpha e_t, & \text{if } y_{t-1} > y_{t-1}^{\text{ind}}(e_t). \end{cases}$$

Defining $\beta \equiv (1 + r)(1 - \alpha)$ and $\beta' \equiv (1 + r')(1 - \alpha)$, with $\beta' > \beta$, this expression can be rewritten in a form analogous to specifications commonly used in the empirical intergenerational mobility literature, which typically models the relationship between parent and child income as linear in levels or in logs. In our case, this relationship features a structural non-linearity associated with a discrete change in slope beyond a

threshold level of parental income:

$$y_t = \begin{cases} \beta y_{t-1} + \alpha e_t, & \text{if } y_{t-1} \leq y_{t-1}^{\text{ind}}(e_t), \\ \beta' y_{t-1} + \alpha e_t, & \text{if } y_{t-1} > y_{t-1}^{\text{ind}}(e_t). \end{cases}$$

This framework naturally connects to the empirical literature on intergenerational mobility, which summarizes economic persistence across generations through the intergenerational elasticity of income (IGE). In that approach, the IGE measures the sensitivity of children’s income to variations in parental income and is interpreted as an aggregate indicator of economic mobility within a society.

In our model, however, this elasticity is not homogeneous across the parental income distribution. Intergenerational transmission operates through distinct regimes: for relatively low-income families, children’s income responds moderately to changes in parental income; in contrast, once parental income exceeds a critical threshold, this response becomes substantially stronger, reflecting higher marginal returns to human capital investment. This structure generates greater intergenerational persistence at the upper end of the income distribution.

As a consequence, intergenerational persistence implied by the model is higher at the top of the income distribution than in the middle, giving rise to an intergenerational elasticity of income (IGE) that varies endogenously along the distribution. This non-linearity provides a structural interpretation of the literature documenting non-linear intergenerational relationships (Black and Devereux 2011; Durlauf and Seshadri 2018; Becker, Kominers, Murphy, and Spenkuch 2018), as well as of empirical evidence identifying these patterns in Latin America (Leites, Ramos, Rodríguez, and Vilá 2022; Cortés Orihuela, Díaz, Gutiérrez Cubillos, Troncoso, and Villarroel 2024) and in developed economies (Bratsberg, Røed, Raaum, Naylor, Jäntti, Eriksson, and Österbacka 2007; Berrittella and Dardanoni 2016; Gregg, Macmillan, and Vittori 2019).

In particular, findings documenting non-linearities in intergenerational income transmission in European and Latin American contexts suggest that international comparisons based exclusively on aggregate mobility measures, such as IGE, may be misleading. The presence of non-linearities implies that economies with similar aggregate IGE levels can exhibit substantially different patterns of intergenerational persistence along the income distribution, especially at the upper end, where increasing returns to human capital are concentrated.

4 Future Work

A first avenue for extension is to explain the rise in income inequality endogenously, through increases in the returns to human capital investment at high levels of accumulation. In this regard, Becker and Tomes (1979) generate inequality using the coefficient

of variation as a measure of income dispersion. However, their approach relies on the assumption that the intergenerational income process along a dynasty $\{y_0, y_1, y_2, \dots\}$ is stationary.

In the model proposed in this paper, stationarity is difficult to sustain. The presence of regime changes in returns to human capital tends to persistently alter the income distribution, generating dynamics that may amplify inequality over time. One possible way to restore stationarity is to introduce income components that are not directly linked to parental investment decisions, such as idiosyncratic productivity shocks, luck components, or government transfers, which may act as countervailing forces in the intergenerational transmission process. Despite these challenges, the stationarity assumption remains conceptually useful for deriving closed-form expressions and for the analysis of inequality (Becker and Tomes 1979; Solon 1999; Solon 2004; Bratsberg, Røed, Raaum, Naylor, Jäntti, Eriksson, and Österbacka 2007).

A second important extension concerns the introduction of taxation. The tax system can modify the relevant slopes of the parent’s budget constraint and, consequently, alter incentives to invest in human capital. In particular, progressive income taxation may attenuate the effective returns to human capital at the upper end of the income distribution, reducing or even eliminating regimes of increasing returns and bringing the intergenerational income relationship closer to the classical linear case. This extension opens the possibility of linking the properties of intergenerational mobility to the degree of tax progressivity across countries. It is plausible that countries exhibiting more linear intergenerational income relationships are characterized by high marginal tax rates at the top of the income distribution, although this remains to be explored.

In this context, it is natural to study how changes in marginal income tax rates affect the shape of the intergenerational transmission and, in particular, how such changes are reflected in the geometry of the parental investment problem illustrated in this paper. This line of research would allow the theoretical model to be connected to observable institutional variation and to comparative evidence on intergenerational mobility.
